To the Editor:

Seborrheic keratosis is one of the most common benign epidermal tumors in dermatologic clinical practice. Although the association between seborrheic keratosis and other skin tumors was first reported in 1932, its malignant transformation is very rare, with less than 20 published cases. We present the case of a patient with seborrheic keratosis that underwent transformation into an invasive squamous cell carcinoma.

The patient was a 94-year-old woman who was seen in our outpatient clinic for a tumor on the abdomen that had been present for 30 years and that had increased in size over a period of months, causing pain and bleeding. On physical examination, a seborrheic keratosis with a maximum diameter of 12 cm was observed. On this lesion there were several hemorrhagic, lobulated tumors (Figure 1). Complete excision of the lesion was performed, with closure by tissue planes and primary suture under local anesthesia. Microscopic examination revealed different histological patterns within the same lesion (Figures 2 and 3), with images characteristic of ulcerated seborrheic keratosis, areas of transition between seborrheic keratosis and Bowen disease, and zones where Bowen disease infiltrated the dermis (invasive squamous cell carcinoma). The histological diagnosis was of invasive squamous cell carcinoma on seborrheic keratosis. Genotyping for human papillomavirus (HPV) was positive for type 59 in 1 of the 4 blocks sent. The patient remains disease-free after 1 year of follow-up in our clinic.
Clinical Science Letters

squamous cell carcinoma, the incidence is higher in men with long-standing lesions situated on the head, neck, or other areas exposed to sunlight.

The molecular mechanism of this transformation is not fully understood. A number of theories implicate the proteins involved in regulation of the cell cycle, alterations of which could lead to the appearance of other tumors. Carcinoembryonic antigen, growth hormone, and proteins p63, BCL2, and BCL6 have also been implicated in the pathogenesis of malignant change. In addition, the role of HPV in the appearance of squamous cell carcinoma is well known. In our case, HPV type 59 was detected in one of the blocks sent for study. This is a strain with a high oncogenic risk, although the viral load in the samples was very low.

In conclusion, rapid growth or transformation of seborrheic keratosis may be a sign of the appearance of a squamous cell carcinoma. In these cases, adequate and complete excision of the lesion is recommended.

Facial Dystrophic Calcinosis Cutis Secondary to Acne

T. Saavedra, F. Mardones, I. Sazunic, and X. Wortsman
Departamento de Dermatologia, Hospital Clínico, Universidad de Chile, Santiago, Chile

To the Editor:

Acne is a common condition in the general population, mainly affecting older children and adolescents. Physical sequelae such as scarring and pigmentation disorders are often observed. However, other secondary lesions such as cutaneous calcification are occasionally reported in the literature. Calcinosis cutis occurs due to the deposition of calcium and phosphate salts in the skin and, in general, can develop around localized tissue damage or in association with systemic metabolic disorders. It is classified into 4 groups according to its etiology: dystrophic, metastatic, iatrogenic, and idiopathic; in some cases different mechanisms can coexist.

We present 2 cases of dystrophic calcinosis cutis of the face as a sequela of inflammatory acne. The patients were women of 48 and 58 years of age, with no past history of note. Both patients reported that they had had severe inflammatory acne during adolescence, mainly affecting the face, making particular mention of the repetitive traumatic manipulation of the facial lesions. They attended our department for treatment of the residual scars on their faces.
