Introduction

Penicilliosis is an infection caused by Penicillium marneffei, a thermally dimorphic fungus. At room temperature (25 °C), it exhibits morphology characteristic of a mold, but grows in yeast-form when found in host tissues or in culture at 37 °C. P. marneffei is limited geographically to Southeast Asia, Southern China, Hong Kong and Taiwan. Although it has been suggested that bamboo rats are a reservoir for this fungus, the specific reservoir for transmission to humans remains unclear.

In man, P. marneffei is an opportunistic fungus that affects HIV-positive and other immunocompromised patients. Ingestion or inhalation of fungus conidia could be the mode of transmission. Although the most common forms of presentation are non-specific and consist of low-grade fever, weight loss and anemia, the characteristic skin lesion is a central umbilicated papule. Since it is usually present, it is an important key to diagnosis.1 Respiratory symptoms occur in around one third of patients, and diffuse reticulo-nodular, diffuse reticular, localized alveolar or localized reticular infiltrates, as well as cavitated lesions, can be identified on chest radiographs.2 We describe the case of an immunocompromised patient who presented with obstruction of the right lower lobe bronchi caused by penicilliosis. We also present a literature review of this very rare condition.

Case Report

In April 2013, a 26-year-old man came in with fever and productive cough. He had been diagnosed with systemic lupus erythematosus (SLE) in 2002 on the basis of a malar rash, positive anti-nuclear antibody and anti-double-stranded DNA antibody

tests, and class IV lupic nephritis with rapidly progressive glomerulonephritis. His symptoms improved following corticosteroid and azathioprine treatment, which was gradually tapered off until it was discontinued in 2010. Two years later, the patient presented cervical lymphadenopathies. *Mycobacterium abscessus* was identified in lymph node and blood cultures. Treatment was established with clarithromycin, doxycycline and levofloxacin. Six months later, the blood cultures were negative for *Mycobacterium*, and the lymphadenopathies had regressed.

When the patient first came to the clinic, he had fever, with a body temperature of 38.2 °C and normal oxygen saturation (SpO2 99%). Physical examination revealed fine crackles in the right lower lobe, but was otherwise unremarkable. There were no signs of skin lesions, lymphadenopathies or hepatomegaly.

Laboratory test results showed mild leukocytosis, normal routine serum biochemistry and negative HIV serology. Chest radiograph revealed a mottled ground glass opacity and consolidation at the level of the right lower lobe (Fig. 1A). Sputum Gram-staining and acid-fast bacilli testing were negative. Empirical treatment for bacterial pneumonia with imipenem–cilastatin was started, but the patient’s clinical condition and chest radiograph did not improve. Chest computed tomography (CT) showed a consolidation in the right lower lobe and luminal stenosis of the basal segmented bronchi (Fig. 1B). There were also multiple small mediastinal lymph nodes.

Bronchoscopy performed one day later showed a whitish endobronchial mass at the opening of the basal anterior, lateral and posterior segmented bronchi of the right lower lobe (Fig. 1C). Histopathological examination of the endobronchial biopsy revealed acute and chronic inflammation with no granuloma formation. However, Grocott methenamine silver (GMS) staining showed a sausage-shaped yeast-type organism, long and oval with clear central septa. Tissue and bronchial lavage cultures were positive for *P. marneffei*.

The patient was treated with intravenous amphotericin B (1 mg/kg/day). The fever subsided after 5 days, and after 2 weeks treatment was switched from intravenous amphotericin B to oral itraconazole (400 mg/day). Two months later, the follow-up chest radiograph showed notable improvement in the lesions in the right lower lobe (Fig. 1D). The follow-up CT scan revealed only minimal residual ground glass opacity, interstitial thickening and slight peribronchial thickening in the previously affected areas (Fig. 1E). Repeat bronchoscopy showed complete resolution of the endobronchial lesion (Fig. 1F). After 6 months, oral itraconazole treatment was reduced to 200 mg/day for prophylaxis.

Given the patient’s history of 2 opportunistic infections (*M. abscessus* and *P. marneffei*) despite all immunosuppressant drugs having been discontinued for 2 years, underlying immunodeficiency was suspected. Anti-interferon-gamma (IFN-γ) antibodies were analyzed, confirming the diagnosis of adult-onset immune deficiency.3

**Discussion**

Endobronchial fungal infection is a very rare manifestation compared to other forms of presentation of fungal lung infections. The most common fungi causing endobronchial infection are *Aspergillus* spp., *Coccidioides immitis*, zygomycetes, *Candida* spp., *Cryptococcus neoformans* and *Histoplasma capsulatum*.4 Endoscopic findings differ in the various fungi, but definitive diagnosis requires microbiological identification (smears, culture or histopathology sections). Pulmonary penicilliosis usually manifests as parenchymal or interstitial lesions. Endobronchial penicilliosis is much rarer. It can occur in immunocompromised hosts with or without HIV, and
even in immunocompetent hosts. As far as we know, there have only been 4 cases in HIV patients, one case in an HIV-negative immunocompromised patient, and one case in an immunocompetent patient reported in English language publications (Table 1).

The characteristics of patients with endobronchial penicilliosis described in case reports essentially did not differ in terms of their underlying immune conditions. The duration of symptoms varied from days to months. All cases involved fever and cough. Extrapulmonary involvement was also identified. The locations of the endobronchial lesions were quite non-specific, ranging in size and characteristics from a small papule, nodule or spot to a mass obstructing the airways.

All patients responded well to anti-fungal medication, and fever generally subsided within 1 week with treatment. The chest radiographs gradually improved over a period of months, leaving some residual infiltrates.

Adult-onset immunodeficiency should be suspected in HIV-negative patients who present repeated episodes of infections caused by rare intracellular pathogens, namely, nontuberculous mycobacteria (NTM), fungal infections (e.g. cryptococcosis, histoplasmosis, penicilliosis), disseminated herpes zoster infection and non-typoid Salmonella bacteremia that cannot be explained by any underlying acquired immunodeficiency, and who are not taking immunosuppressive drugs. Lastly, positive IFN-γ autoantibodies are the hallmark for diagnosis. IFN-γ plays an important role in the cellular immune response by activating macrophages to phagoctyes and destroy intracellular pathogens. An IFN-γ deficiency, therefore, would impair the ability of the macrophages to destroy the intracellular microorganism. Our patient was diagnosed with SLE, which is also an autoimmune disease. Although autoantibodies play an important role in both SLE and adult-onset immunodeficiency, they target different cells. As far as we are aware, there have been no published cases in which a correlation between these 2 diseases is mentioned. Consequently, the coexistence of SLE and adult-onset immunodeficiency in our patient could be a coincidence.

In conclusion, we present a case of endobronchial penicilliosis in a patient with adult-onset immunodeficiency. As this is a very rare respiratory manifestation, extensive medical knowledge is needed for the physician to bear in mind this particular infection, and to request the best examination (bronchoscopy) to reach a definitive diagnosis.
